Jiangsu Key Laboratory of Atmospheric Environment Monitoring and Pollution Control, Jiangsu Collaborative Innovation Center of Atmospheric Environment and Equipment Technology, School of Environmental Science and Engineering, Nanjing University of Information Science and Technology, Nanjing, China

We applied the global 3-D chemical transport model GEOS-Chem to examine the effects of changes in anthropogenic emissions over China on PM_{2.5} concentrations in South Korea and Japan over 2013–2017 during which the Chinese governmental “Action Plan on the Prevention and Control of Air Pollution” was implemented. The reductions in anthropogenic emissions in China alleviated PM_{2.5} concentrations in South Korea and Japan. The reductions in anthropogenic emissions in China alone led to reductions in annual mean PM_{2.5} concentrations by 13.7 (19.7%), 2.7 (7.7%), and 1.0 (7.9%) $\mu\text{g m}^{-3}$ over 2013–2017 in eastern China, South Korea, and Japan, respectively. The reductions in anthropogenic emissions in China also changed the components of PM_{2.5} in South Korea and Japan. The concentrations of sulfate, ammonium, black carbon and organic carbon were simulated to decrease and those of nitrate were simulated to increase in both South Korea and Japan. With the changes in anthropogenic emissions and the changes in meteorology (BASE simulation), the proportions of sulfate, nitrate, and OC in PM_{2.5} in South Korea (Japan) were, respectively, 17.1, 44.4, and 15.8% (27.2, 30.5, and 20.0%) in 2013, and 14.3, 46.0, and 17.8% (23.7, 33.2, and 21.6%) in 2017. Model results shown here are helpful for understanding the temporal evolution in PM_{2.5} on different timescales in the downwind regions of China.

1 INTRODUCTION

Air pollution is a serious environmental problem that influences human health, ecosystem, and climate (IPCC, 2021). The Chinese government issued the “Action Plan on the Prevention and Control of Air Pollution” in 2013 to aggressively control anthropogenic emissions thereafter. With the implementation of a series of stringent air pollution control measures, the observed annual mean PM_{2.5} concentrations from the China National Environmental Monitoring Center (CNEMC) showed decreases in PM_{2.5} concentrations by 34–49% over 2013–2018 in the five megacity clusters (Beijing–Tianjin–Hebei, Yangtze River Delta, Pearl River Delta, Fenwei Plain, and Sichuan Basin) (Zhai et al., 2019). Because of the prevailing westerlies in Northeast Asia, it is of interest to examine how the changes in anthropogenic emissions in China can influence air quality in the downwind areas, especially in Japan and South Korea, through the long-range transport of air pollutants.

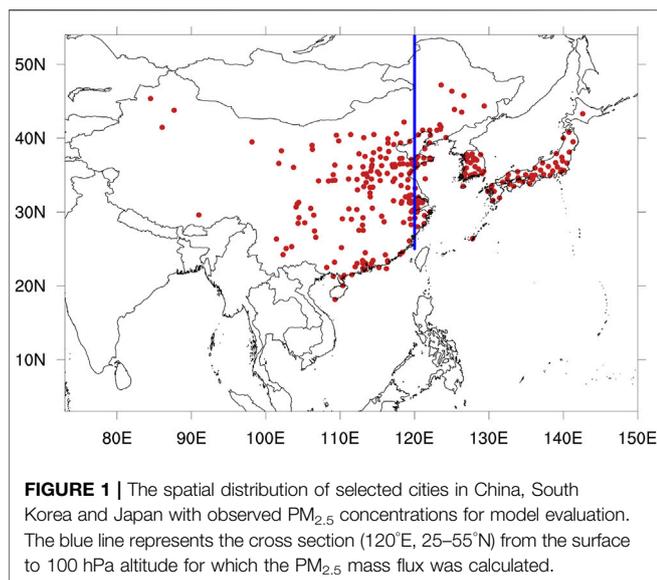

A number of observational and modeling studies have demonstrated the influence of long-range transport of aerosols from China on aerosol levels in South Korea and Japan. Lee et al. (2018) selected four long-lasting haze episodes (all in winter) occurred in South Korea during 2009–2014 using aerosol optical depth (AOD) at 550 nm from Terra and Aqua Moderate Resolution Imaging Spectroradiometer (MODIS). The distributions of AODs over northeast Asia during each episode showed that the high-AOD area moved from China to South Korea in the presence of northwesters or westerlies. Similarly, Lee et al. (2019) examined three representative cases during the Korea-United States Air Quality (KORUS-AQ) campaign from 1 May to 12 June 2016 by using the hourly Geostationary Ocean Colour Imager (GOCI) AOD images. They found that the heavy aerosol plumes generated in central-eastern China (particularly in the Shandong peninsula) could pass across the Yellow Sea, and then reached the middle to northern South Korea. Park et al. (2018) collected PM_{2.5} samples in Seoul, South Korea, from September 2013 to May 2015 and in Nagasaki, Japan, from February 2014 to May 2015 to analyze the 72-h backward trajectories of aerosols. For Seoul, 62% of total trajectories originated from the Yellow Sea near the industrial area in Liaoning Province in China and then moved to the southwestern of Seoul. For Nagasaki, 61% of total trajectories originated from northern China (near Beijing) and passed through North Korea and South Korea to Nagasaki. Aikawa et al. (2010) used a 3-dimensional regional chemical transport model to estimate the impact of transboundary transport on sulfate concentrations at 24 sites in urban, suburban, and rural areas of Japan. They performed simulations with and without anthropogenic emissions in China from 1 January 2003 to 31 March 2006, and reported that Chinese emissions contributed 50–70% to modeled 3-year mean sulfate concentrations at 24 sites in Japan, with a maximum of about 65–80% in winter. Lee et al. (2017) examined PM_{2.5} concentrations in 10 PM_{2.5} episodes (both modeled and measured PM_{2.5} concentrations exceeded the daily air quality standard of 50 µg m⁻³) in May of 2009–2013 using the GEOS-Chem model, and found that anthropogenic emissions from Shandong Province in China had the largest modeled influence on PM_{2.5} in Seoul in May. Averaged over the 10 episodes, 69% of simulated PM_{2.5} in Seoul were from China (39% from the Shandong Province, 16% from Shanghai, and 14% from the Beijing). Yim et al. (2019) used the Weather Research and Forecasting Model (WRF) and Community Multiscale Air Quality Modeling System (CMAQ) to simulate the contributions of anthropogenic emissions in China to PM_{2.5} in South Korea and Japan in 2010 by sensitivity studies. Anthropogenic emissions in China were estimated to contribute 54% to annual mean surface concentrations of PM_{2.5} in both Japan and South Korea in 2010. In Japan, the highest contribution from China occurred in spring (61.4%), followed by winter (55.1%) and summer (50.5%), and autumn (44.0%). In South Korea, the contributions of Chinese emissions were higher in winter (62.9%) and spring (55.5%), while lower in autumn (51.7%) and summer (43.8%). Kumar et al. (2021) used the GEOS-Chem model to estimate source attribution to PM_{2.5} in South

Korea from international and domestic emissions in 2015 and 2016 by sensitivity simulations. Their results showed that, on an annual mean basis, anthropogenic emissions in China contributed 45% to PM_{2.5} in South Korea in 2016, which was 3–5% lower than the Chinese contribution in 2015 because of emissions reductions in China. Results from these studies indicate that the air quality in South Korea and Japan is closely related to air pollution in China.

The long-range transboundary transport of air pollutants (LRTT) is an important issue in air quality planning. East Asia is located in the warm conveyor belts (WCBs) of mid-latitude storm tracks, where airstreams rapidly transport the atmospheric boundary layer air into the upper troposphere by convection, orographic lifting, frontal lifting and ascension (Stohl et al., 2002; Eckhardt et al., 2004). The analysis of meteorological conditions for heavy pollution episodes in South Korea showed that the anomalous low pressure over the upwind regions lifted air pollutants into the upper troposphere, then the strong persistent westerlies in this region driven the flow of pollutants (Qu et al., 2016). When the outflow of air pollutants arrives at South Korea and Japan, the anomalous high pressure causes the air to descend and leads to the accumulation of pollutants in these regions (Lee et al., 2011; Lee et al., 2018).

There were several studies that examined the effects of changes in outflow from China in recent years on aerosol levels in Japan and South Korea. Bhardwaj et al. (2019) carried out the multi-year trend analysis for observed AOD, CO and SO₂ with a special focus on the Yellow Sea region. They showed that percentage changes in AOD over 2012–2016 were -23.7%, -11.7% and -16.5% over the North China Plain, Yellow Sea, and South Korea, respectively, and the surface CO mixing ratios over 2012–2016 decreased by 8.3, 5.1 and 3.9%, respectively, in these three regions. Kanaya et al. (2020) analyzed the changes in black carbon (BC) and PM_{2.5} over 2009–2019 at Fukue island in Japan, and reported that concentrations of BC and PM_{2.5} decreased by 48 and 21%, respectively. Uno et al. (2020) reported that the observed surface-layer PM_{2.5} in Japan decreased in recent years, and the proportion of stations that satisfied the PM_{2.5} air quality standard increased from 37.8% in 2014 to 89.9% in 2017. Bae et al. (2021) showed that, from 2015 to 2018, the observed PM_{2.5} concentrations averaged over 344 monitoring stations across South Korea decreased by 4.3% per year and the MODIS AOD in South Korea decreased by 4.7% per year. They also used the Community Multiscale Air Quality (CMAQ) model to quantify the impacts of the emissions and meteorology on the PM_{2.5} concentration over 2015–2018. Their results showed that the changes in emissions and meteorology over 2015–2018 contributed 51 and 49%, respectively, to the reductions in PM_{2.5} in South Korea. Previous studies, however, did not quantify the influence of air quality improvement in China on air quality in the downwind regions.

In this study, we examined the effects of reductions in anthropogenic emissions reductions in China over 2013–2017 on PM_{2.5} concentrations in downwind areas (South Korea and Japan) through the long-range transport of air pollutants. The scientific goals of this work include: 1) to quantify the influence of

anthropogenic emissions reductions in China on PM_{2.5} in South Korea and Japan by using the global chemical transport model GEOS-Chem; 2) to distinguish the impacts of changes in meteorological fields and/or anthropogenic emissions on PM_{2.5}; 3) to understand the seasonal characteristics of PM_{2.5} changes in South Korea and Japan.

2 MATERIALS AND METHODS

2.1 Observed PM_{2.5} Concentrations

We use PM_{2.5} concentrations observed in 199 cities in provinces across China. The monthly PM_{2.5} concentrations in 199 cities during 2014–2017 were obtained by averaging the hourly data of each city from the China National Environmental Monitoring Center (<http://www.cnemc.cn/>). Observed PM_{2.5} concentrations in 2013–2017 in Japan were collected from the National Institute for Environmental Studies (<http://www.nies.go.jp/igreen/>), which provides PM_{2.5} observations in 47 prefectures across Japan. The monthly mean PM_{2.5} in all 47 regions are available from this website. The observation of PM_{2.5} in South Korea started in 2015. The observed PM_{2.5} concentrations in 2015–2017 were downloaded from the official Air Korea website of the Ministry of Environment of Korea (<http://www.airkorea.or.kr>). We selected 30 cities from this website which had continuous and valid monthly averaged observation data (the percentage of observation days in a month is greater than 50%). The locations of cities in China, South Korea and Japan are shown in **Figure 1**.

2.2 Model Description

For simulation of aerosols in East Asia, we used the 3-D Goddard Earth Observing System chemical transport model (GEOS-Chem) which includes fully coupled HO_x-NO_x-VOC-O₃-aerosol chemistry with more than 80 species and 300 reactions and online calculations of aerosols including sulfate (Park et al.,

2004), nitrate (Pye et al., 2009), ammonium, BC and organic carbon (OC) (Park et al., 2003), mineral dust (Fairlie et al., 2007), and sea salt (Alexander et al., 2005). We simulated concentrations of aerosols using the nested-grid version of the GEOS-Chem model version 11-01 (<http://acmg.seas.harvard.edu/geos/>) driven by Modern-Era Retrospective Analysis for Research and Applications Version (MERRA-2) assimilated meteorological fields from NASA's Global Modeling and Assimilation Office (GMAO) (Gelaro et al., 2017). The nested domain for Asia (60–150°E, 11°S–55°N) has 47 vertical layers up to 0.01 hPa and a horizontal resolution of 0.5° latitude by 0.625° longitude. Both wet deposition of soluble aerosols and gases (Liu et al., 2001) and dry deposition (Wesely, 2007) are included in the model simulation. PM_{2.5} concentration is calculated as the sum of sulfate, nitrate, ammonium, BC, and OC from the model. We do not consider sea salt and mineral dust aerosols in PM_{2.5} in this study.

2.3 Emissions

The NO_x emissions from soil and lighting were calculated online based on MERRA-2 meteorology. Biomass burning emissions followed the Global Fire Emissions database Version 4 (van der Werf et al., 2017), and biogenic emissions of volatile organic compounds (VOCs) were calculated online by Model of Emissions of Gases and Aerosols from Nature Version 2 (Guenther et al., 2006). We used anthropogenic emissions from the Community Emissions Data System (CEDS) (Hoesly et al., 2018) for the global domain during 2013–2017, overwritten by year-specific Multi-resolution Emission Inventory for China (MEIC) (Zheng et al., 2018) over China and Regional Emission inventory in Asia (REASv3.2) (Kurokawa and Ohara, 2020) over other regions of East Asia. The anthropogenic emissions from REAS in 2016 and 2017 were obtained by linear extrapolation of values over 2012–2015 for each grid. The anthropogenic emissions mainly come from five sectors of agriculture, power, transportation, industry and residential.

Table 1 shows the summary of annual anthropogenic emissions of aerosols and aerosol precursors in China from MEIC and in South Korea and Japan from REASv32 during 2013–2017. As the result of air pollution control policies, anthropogenic emissions of all species except non-methane volatile organic compounds (NMVOCs) decreased year by year over China from 2013 to 2017, with largest reductions in the North China Plain (NCP) and the Yangtze River Delta (YRD) (see **Supplementary Figure S1**). The reduction in emissions of SO₂ was the largest, with a decrease of 58.7% over 2013–2017. Over 2013–2017, the emissions of NO_x, CO, NH₃, BC and OC in China were reduced by 20.7, 22.9, 3.4, 28.2 and 32.4%, respectively. In South Korea, over 2013–2017, the annual anthropogenic emissions of BC and NO_x decreased, while other anthropogenic emissions increased, especially those of OC. In Japan, the anthropogenic emissions kept decreasing year by year during 2013–2017, the annual anthropogenic emissions of NO_x, CO, NMVOCs, SO₂, NH₃, BC and OC in Japan decreased by 20.0, 17.7, 12.5, 21.9, 4.9, 30.7 and 12.7%, respectively.

TABLE 1 | Summary of annual anthropogenic emissions of aerosols and aerosol precursors in China from MEIC, in South Korea and Japan from REASv32 during 2013–2017 (units: GgC for NMVOCs and Gg for other species).

Country	Year	NO _x	CO	NMVOCs	SO ₂	NH ₃	BC	OC

FIXEM_CKJ	2013–2017	2013	2013	2013	2013

2.4 Numerical Experiments

This study will be focused on aerosol concentrations in China, South Korea and Japan. To investigate the influences of anthropogenic emission reductions in China on air quality over South Korea and Japan, we conducted three 5-year simulations with the GEOS-Chem model with nested domain in Asia (**Table 2**):

1. BASE: The standard simulation with variations of anthropogenic emissions in Asia and meteorological fields over 2013–2017. Anthropogenic emissions outside Asia were fixed at 2013 levels.
2. FIXEM_KJ: Same as BASE simulation except that anthropogenic emissions over regions other than China were fixed at 2013 levels.
3. FIXEM_CKJ: Same as BASE simulation except that anthropogenic emissions over all regions were fixed at 2013 levels.

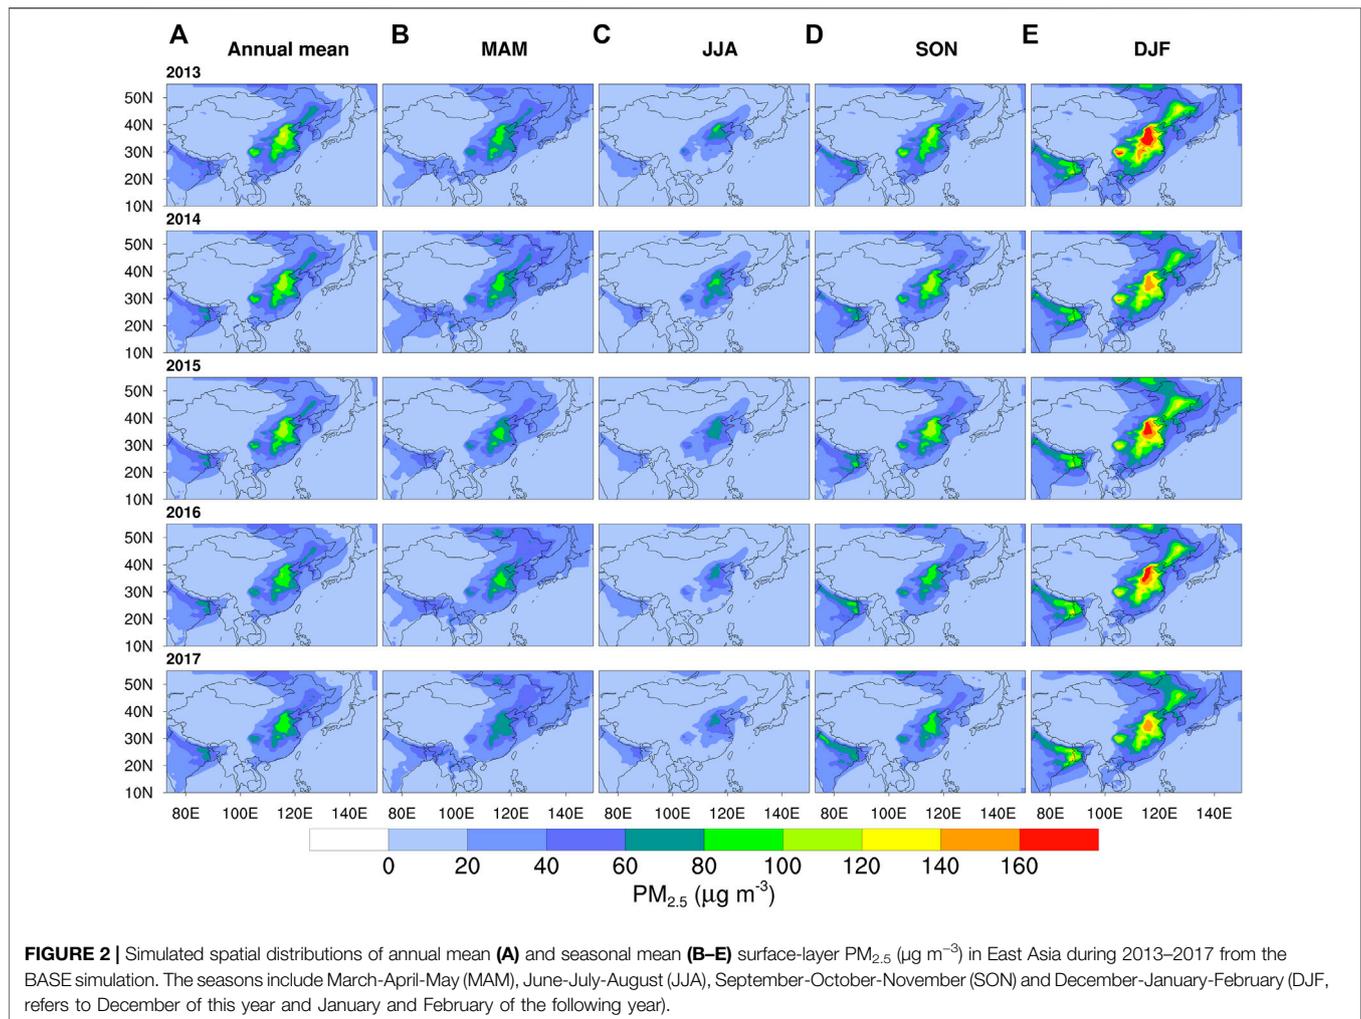

The BASE simulation was used for model evaluation. The FIXEM_CKJ simulation shows the effects of changes in meteorological fields over 2013–2017 alone on aerosol levels in China, South Korea and Japan. The differences between FIXEM_KJ and FIXEM_CKJ (FIXEM_KJ minus FIXEM_CKJ) represent the impacts of changes in anthropogenic emissions in China over 2013–2017 on aerosol concentrations in China, South Korea, and Japan.

3 RESULTS

3.1 Simulated PM_{2.5} Concentration in East Asia From 2013 to 2017

Figure 2 shows the simulated annual and seasonal mean surface layer PM_{2.5} concentrations over East Asia from 2013 to 2017 from the BASE simulation. The simulated annual mean PM_{2.5} concentrations in eastern China reached 80–120 μg m⁻³ during 2013–2017. Seasonally, PM_{2.5} concentrations in China were the highest in DJF due to the strengthened anthropogenic emissions as well as the unfavorable weather conditions, and were the lowest in JJA because of the enhanced wet removal from the East Asian summer monsoon (Zhang et al., 2010). Both the annual and seasonal mean PM_{2.5} concentrations in China exhibited clear decreasing trends over 2013–2017 because of the stringent emission control measures in China. PM_{2.5} concentrations in South Korea were generally higher than those in Japan, the simulated annual mean PM_{2.5} concentrations were in the range of 20–40 μg m⁻³ over South Korea and were 10–20 μg m⁻³ in Japan. PM_{2.5} concentrations over South Korea and Japan had the same seasonal variations, with concentrations higher in DJF and MAM and lower in JJA and SON.

We use the ground-based observations to evaluate the model performance in simulating the surface-layer PM_{2.5} for each year. **Supplementary Figure S2–4** display the spatial distributions of simulated (from the BASE simulation) and observed annual mean PM_{2.5} concentrations in China, South Korea, and Japan.

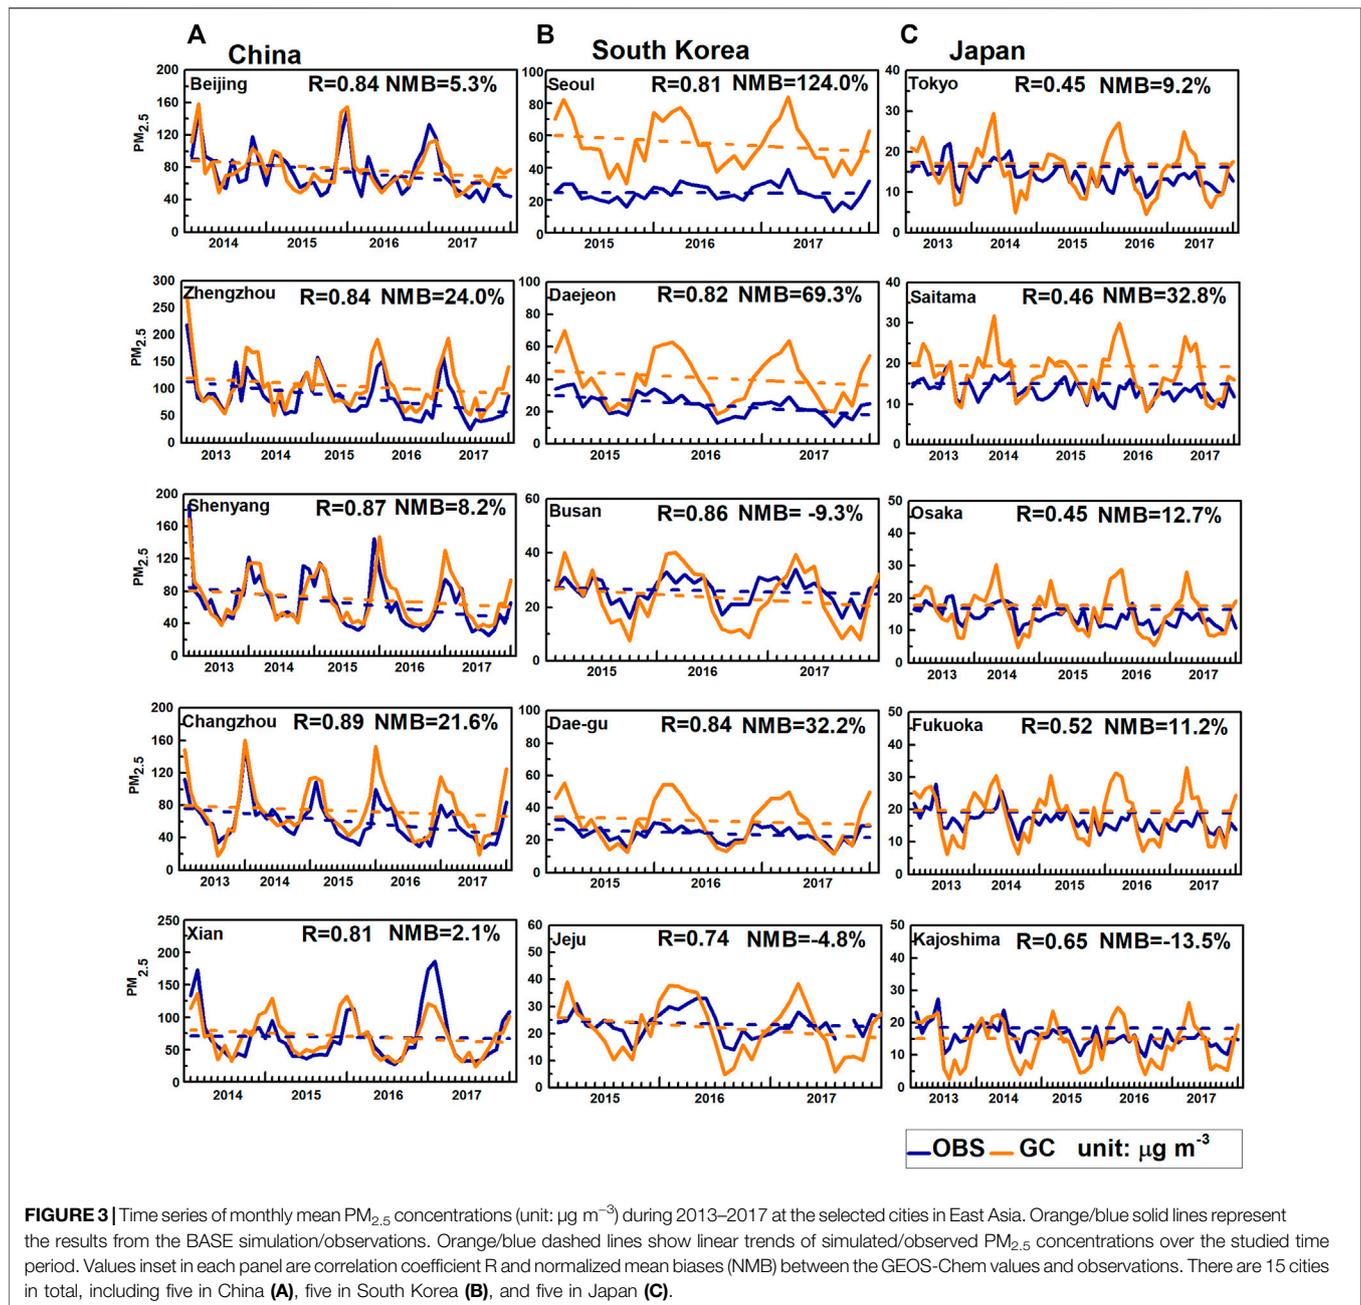

The model can reproduce the spatial distributions of PM_{2.5} concentrations in these three regions. The normalized mean biases (NMBs) between simulated and observed annual mean PM_{2.5} concentrations in China are -0.5 , 9.1 , 8.9 , and 15.1% in years of 2014–2017, respectively. The NMBs of annual mean PM_{2.5} concentrations in South Korea are 25.2 , 34.6 , and 37.5% in years of 2015–2017, respectively, and in Japan are 5.5 , 12.2 , 14.7 , 34.2 , and 34.1% in years of 2013–2017, respectively. Thus the model has high biases in South Korea and Japan during 2016–2017. There might be two reasons for the increasing trend of biases. First, anthropogenic emissions outside Asia were kept at 2013 levels (see **Table 2**). Second, the REAS emission inventory is available only up to 2015, so anthropogenic emissions in South Korea and Japan in 2016 and 2017 were obtained by linear extrapolation of the REAS values over 2012–2015 for each grid. **Figure 3** compares simulated and observed monthly mean PM_{2.5} concentrations at 15 selected cities (5 cities in each of China, South Korea and Japan). Simulated concentrations of PM_{2.5} in China agree fairly well with the observations, with high correlation coefficients of 0.81 – 0.89 and small NMBs of 2.1 – 24.0% in the five cities located in different polluted areas in China. In South Korea, the

model has high biases with NMBs of 32.2 – 124.0% in the western part of South Korea (Seoul, Daejeon and Dae-gu locations, especially in the Seoul metropolitan area), and has small low biases with NMBs of -9.3% and -4.8% in remote areas like Busan and Jeju Island. The NMBs in five cities in Japan are in the range of -13.5 – 32.8% , but the correlation coefficients are relatively smaller (between 0.45 and 0.65) compared to the values in China and South Korea. The seasonal variations of the observed PM_{2.5} in Japanese cities were small, but the simulated results show large seasonal variations. The model well captures the decreasing trends in PM_{2.5} concentrations in all cities except for Seoul and the trends from the model were weaker than those in the observations in some cities.

3.2 Drivers of the 2013–2017 Changes in PM_{2.5} Concentrations

Figure 4 shows the yearly changes in PM_{2.5} in East Asia compared to the previous year. In China, the simulated annual mean PM_{2.5} concentrations in the BASE simulation generally decreased in all years compared to the previous year, except for a partial increase in North China caused by the meteorological

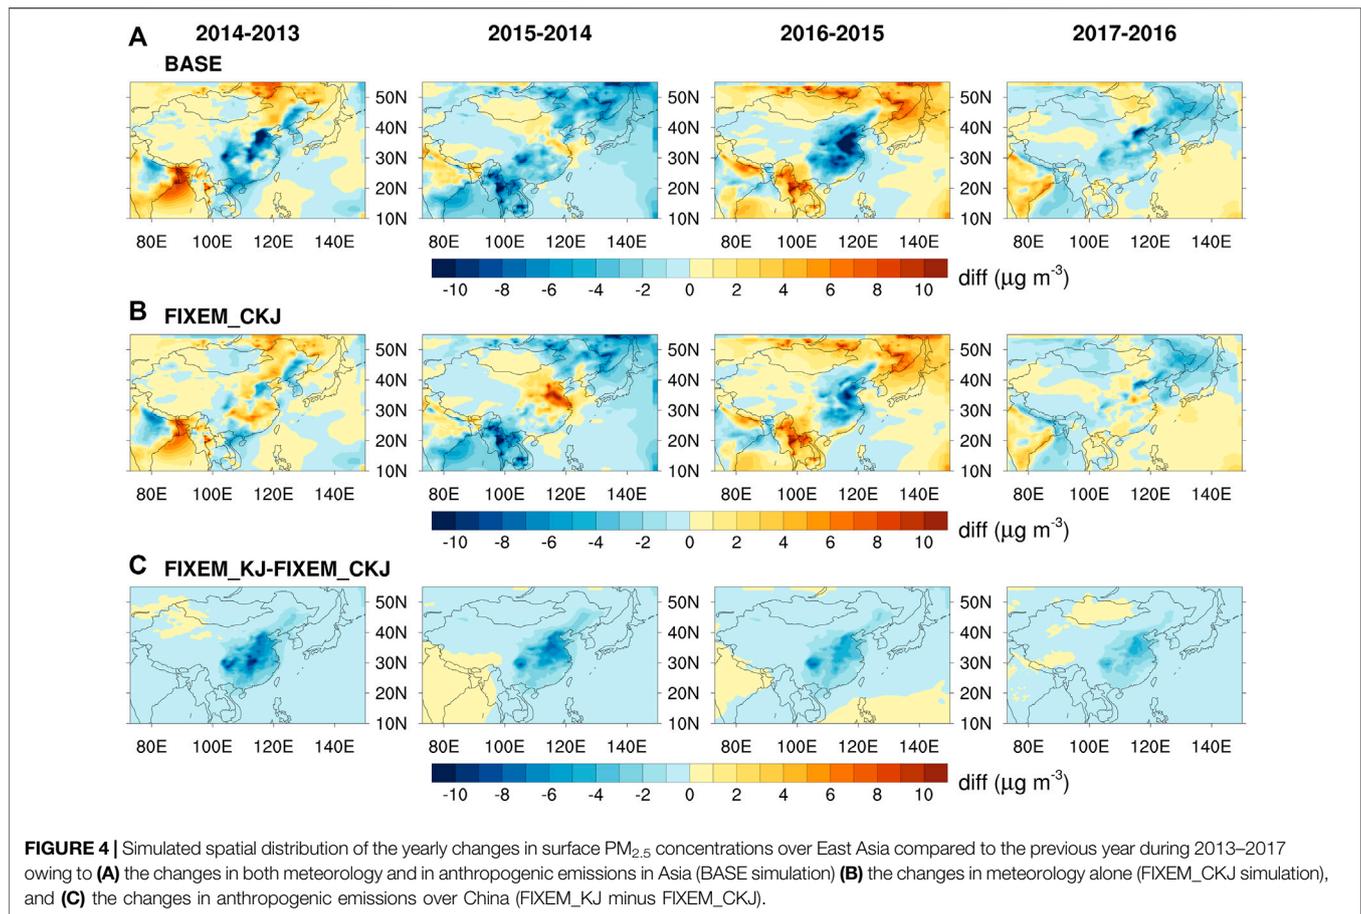

conditions in 2015. In the downwind regions of China, with the changes in both meteorology and anthropogenic emissions, simulated annual mean PM_{2.5} concentrations in the BASE simulation showed overall increases in 2014 and 2016 compared to the previous year whereas decreases in 2015 and 2017. The patterns of simulated year-to-year changes in PM_{2.5} concentrations over South Korea and Japan in BASE simulation were similar to those in FIXEM_CKJ simulation, indicating the dominant influence of meteorology. Changes in anthropogenic emissions over China are estimated to reduce PM_{2.5} levels in China and its downwind regions year by year during 2013–2017 (FIXEM_KJ minus FIXEM_CKJ).

We further analyze the 2013–2017 changes in PM_{2.5} concentrations in eastern China (25–40°N, 110–120°E), South Korea (34.3–38°N, 126.2–129.5°E), and Japan (38–45°N, 139–145°E and 31–38°N, 130–141°E) and attribute these changes to the changes in anthropogenic emissions (FIXEM_KJ minus FIXEM_CKJ) or the changes in meteorological fields (FIXEM_CKJ) (Figure 5).

3.2.1 Eastern China

In the BASE simulation, from 2013 to 2017, the annual mean PM_{2.5} concentrations in eastern China were 69.4, 66.3, 65.4, 58.7, and 56.6 µg m⁻³, respectively. The year by year decreases in PM_{2.5}

concentrations were dominated by the changes in anthropogenic emissions. Relative to 2013, the annual mean PM_{2.5} concentration in 2017 was reduced by $13.7 \mu\text{g m}^{-3}$ from the changes in anthropogenic emission (Figure 5C). The role of meteorology varied with years, which increased PM_{2.5} by $4.0 \mu\text{g m}^{-3}$ in 2015 relative to 2013. Among all seasons, the emission control measures in China were simulated to lead to largest reduction in PM_{2.5} ($-17.6 \mu\text{g m}^{-3}$ in 2017 relative to 2013) in eastern China in DJF. The changes in meteorological conditions had larger impacts on PM_{2.5} concentrations in eastern China in JJA and SON (2.0 – $16.3 \mu\text{g m}^{-3}$) than those in MAM and DJF (-12.2 – $3.6 \mu\text{g m}^{-3}$) (Figure 5B).

3.2.2 South Korea

In the BASE simulation with combined changes in emissions and meteorology, simulated annual mean PM_{2.5} concentration in South Korea had a decreasing trend of $-0.66 \mu\text{g m}^{-3} \text{ year}^{-1}$ over 2013–2017 and the annual mean PM_{2.5} concentration in 2017 was reduced by $3.0 \mu\text{g m}^{-3}$ (8.4%) compared to 2013 (Figure 5A). Over 2013–2017, the meteorological changes alone were estimated to lead to a trend of $-0.3 \mu\text{g m}^{-3} \text{ year}^{-1}$ for PM_{2.5} (Figure 5B), and the changes in anthropogenic emissions in China alone were estimated to lead to a trend of $-0.67 \mu\text{g m}^{-3} \text{ year}^{-1}$ (Figure 5C). Over 2013–2017, the change in PM_{2.5} of $-2.74 \mu\text{g m}^{-3}$ by the changes in anthropogenic emissions

in China contributed 91% to the change in PM_{2.5} concentration in South Korea in the BASE simulation. The impacts of changes in Chinese anthropogenic emissions on PM_{2.5} concentration in South Korea were the largest in JJA, with PM_{2.5} concentration dropped by $3.8 \mu\text{g m}^{-3}$ from 2013 to 2017. The changes in both meteorological conditions and anthropogenic emissions over China led to reductions in PM_{2.5} concentrations in South Korea, but the changes in anthropogenic emissions over China played a leading role.

3.2.3 Japan

Simulated PM_{2.5} concentrations in Japan exhibited a small trend of $-0.09 \mu\text{g m}^{-3} \text{ year}^{-1}$ over 2013–2017 in the BASE simulation. The annual PM_{2.5} concentrations in Japan during 2013–2017 were 13.7 , 13.9 , 12.4 , 13.8 , and $13.3 \mu\text{g m}^{-3}$, respectively. The meteorological changes alone were estimated to lead to an increasing trend of $0.08 \mu\text{g m}^{-3} \text{ year}^{-1}$, although meteorological conditions led to large reduction ($0.84 \mu\text{g m}^{-3}$) in PM_{2.5} in 2015 (Figure 5B). The simulated 2013–2017 trend resulting from changes in anthropogenic emissions over China was $-0.26 \mu\text{g m}^{-3} \text{ year}^{-1}$ (Figure 5C). From 2013 to 2017, the changes in anthropogenic emission in China led to similar changes in PM_{2.5} concentrations in Japan by -1.2 , -1.1 , -1.0 , and $-0.96 \mu\text{g m}^{-3}$ in MAM, JJA, SON and DJF, respectively. Therefore, in Japan, changes in meteorological conditions and

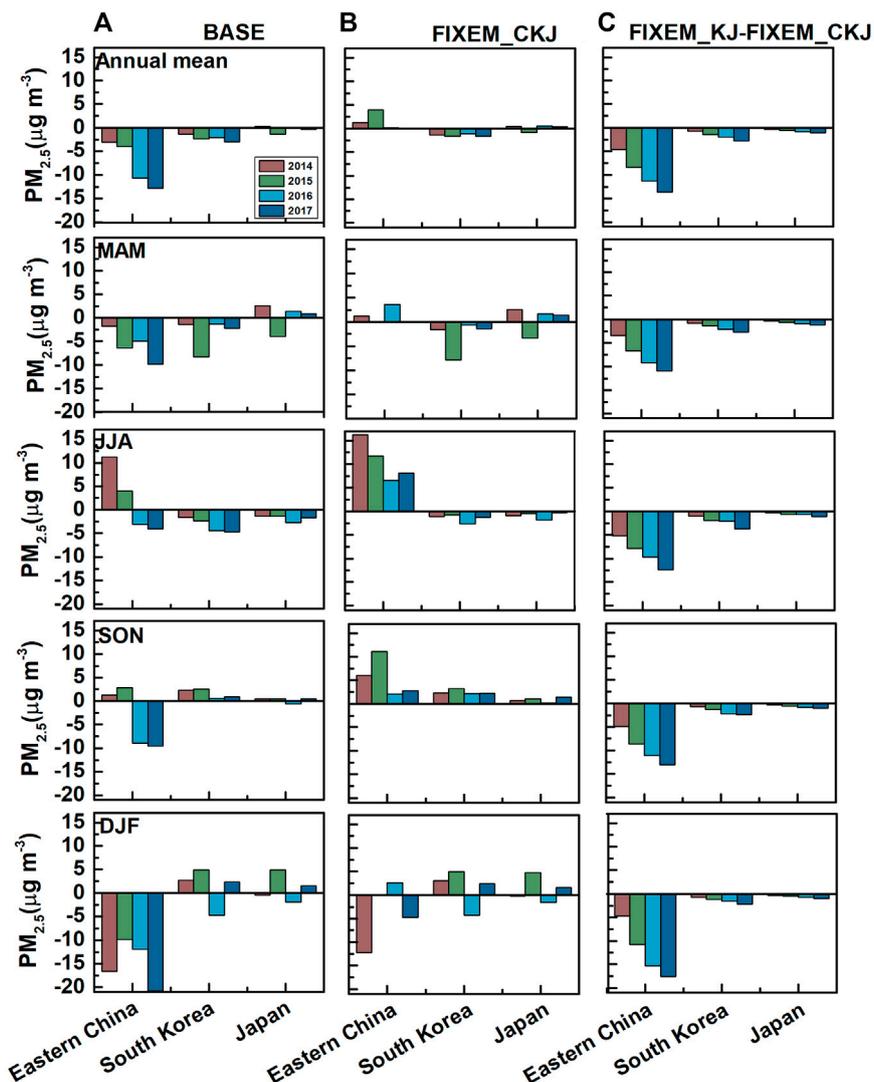

FIGURE 5 | The changes in annual or seasonal mean surface PM_{2.5} concentrations in Eastern China (25–40°N, 110–120°E), South Korea (34.3–38°N, 126.2–129.5°E) and Japan (38–45°N, 139–145°E and 31–38°N, 130–141°E) relative to 2013 owing to (A) the changes in both meteorology and anthropogenic emissions in Asia (BASE simulation) (B) the changes in meteorology alone (FIXEM_CKJ simulation), and (C) the changes in anthropogenic emissions over China (FIXEM_KJ minus FIXEM_CKJ).

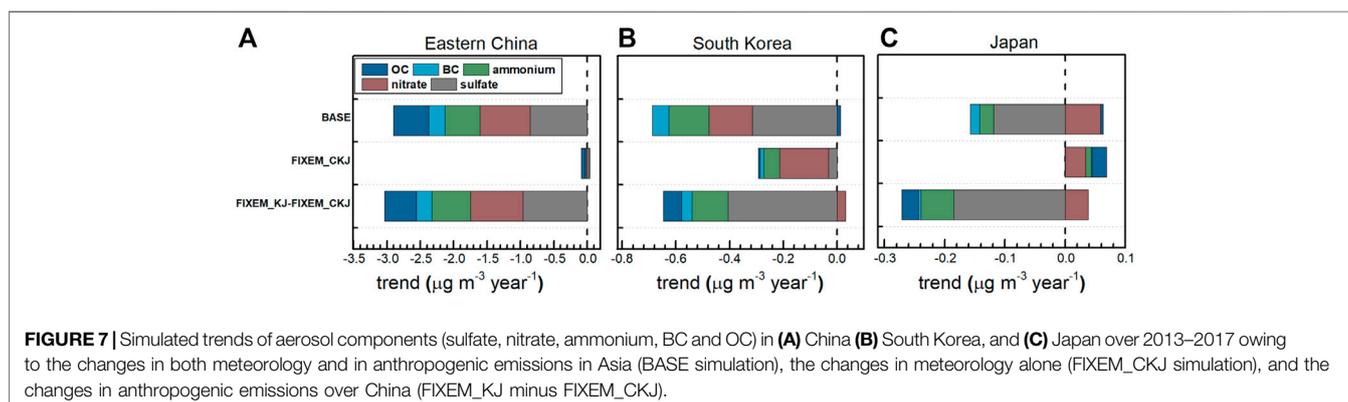

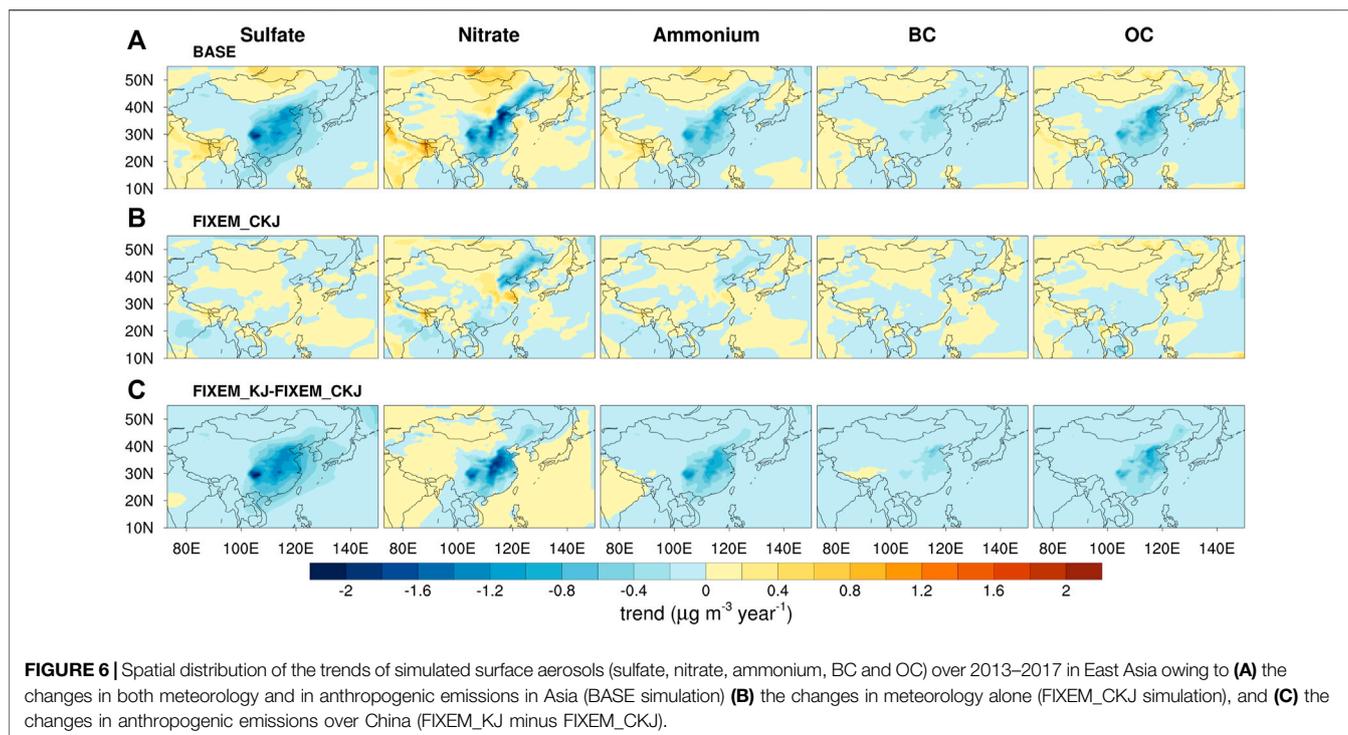

in anthropogenic emissions in China over 2013–2017 had comparable effects on PM_{2.5} concentrations but with opposite signs.

3.3 Drivers of the 2013–2017 Changes in Components of PM_{2.5} in South Korea and Japan

Figure 6 shows the simulated spatial distributions of the trends of concentrations of PM_{2.5} components (sulfate, nitrate, ammonium, BC and OC) over 2013–2017 in East Asia. In the BASE simulation, the concentrations of all aerosol species had downward trends in eastern China, in which sulfate and nitrate had the largest decreases. In the downwind regions of China, sulfate, ammonium, and BC exhibited decreasing trends, nitrate

decreased in South Korea and increased in Japan, and OC concentrations had increasing trends in both South Korea and Japan in the BASE simulation. In the FIXEM_CKJ simulation, the trends of all components caused by changes in meteorological conditions had similar spatial distributions, with negative trends in northeastern and southeastern China and South Korea whereas positive trends in central eastern China and Japan. The changes in anthropogenic emissions in China led to reductions in sulfate, ammonium, BC, and OC in the whole of East Asia. However, nitrate aerosol had an increasing trend in the downwind regions of China.

The regional trends of aerosol components are summarized in Figure 7. The trends of sulfate, nitrate, ammonium, BC and OC in eastern China in the BASE simulation were -0.86 , -0.75 , -0.53 , -0.24 , and $-0.53 \mu\text{g m}^{-3} \text{ year}^{-1}$, respectively, which were much

higher than the trends of decreases in South Korea and Japan (Figure 7). These decreasing trends in eastern China were mainly caused by domestic changes in anthropogenic emissions.

In South Korea, sulfate had the largest decreasing trend ($-0.32 \mu\text{g m}^{-3} \text{ year}^{-1}$), followed by nitrate ($-0.16 \mu\text{g m}^{-3} \text{ year}^{-1}$) and ammonium ($-0.15 \mu\text{g m}^{-3} \text{ year}^{-1}$), in the BASE simulation. The changes in anthropogenic emissions in China led to large reductions in sulfate and ammonium whereas an increase in nitrate. Changes in meteorological conditions led to a relatively large decreasing trend of nitrate in South Korea.

The trends of aerosol components in the BASE simulation in Japan were the smallest among the three countries. The trends of aerosol concentrations influenced by meteorology were positive for all aerosol species. The changes in anthropogenic emissions over China had similar impacts on aerosol components in Japan

as compared to South Korea. Nitrate concentrations increased in Japan from 2013 to 2017 by changes both in anthropogenic emissions in China and in meteorological fields.

To summarize, the changes in anthropogenic emissions over China in 2013–2017 had the largest impacts on sulfate concentrations in South Korea and Japan, leading to large reductions in sulfate. On the contrary, the changes in meteorology had almost no effect on sulfate in South Korea and Japan. Over 2013–2017, anthropogenic emissions of nitrate precursors of NO_x and NH_3 were reduced by 20.7 and 3.4% in China, respectively, and the concentrations of nitrate were reduced in China. However, the changes in anthropogenic emissions over China led to an increasing trend of nitrate in South Korea and Japan, which can be explained by that the reductions in SO_2 emissions changed the balance of the ammonia–nitric acid–sulfuric acid–water

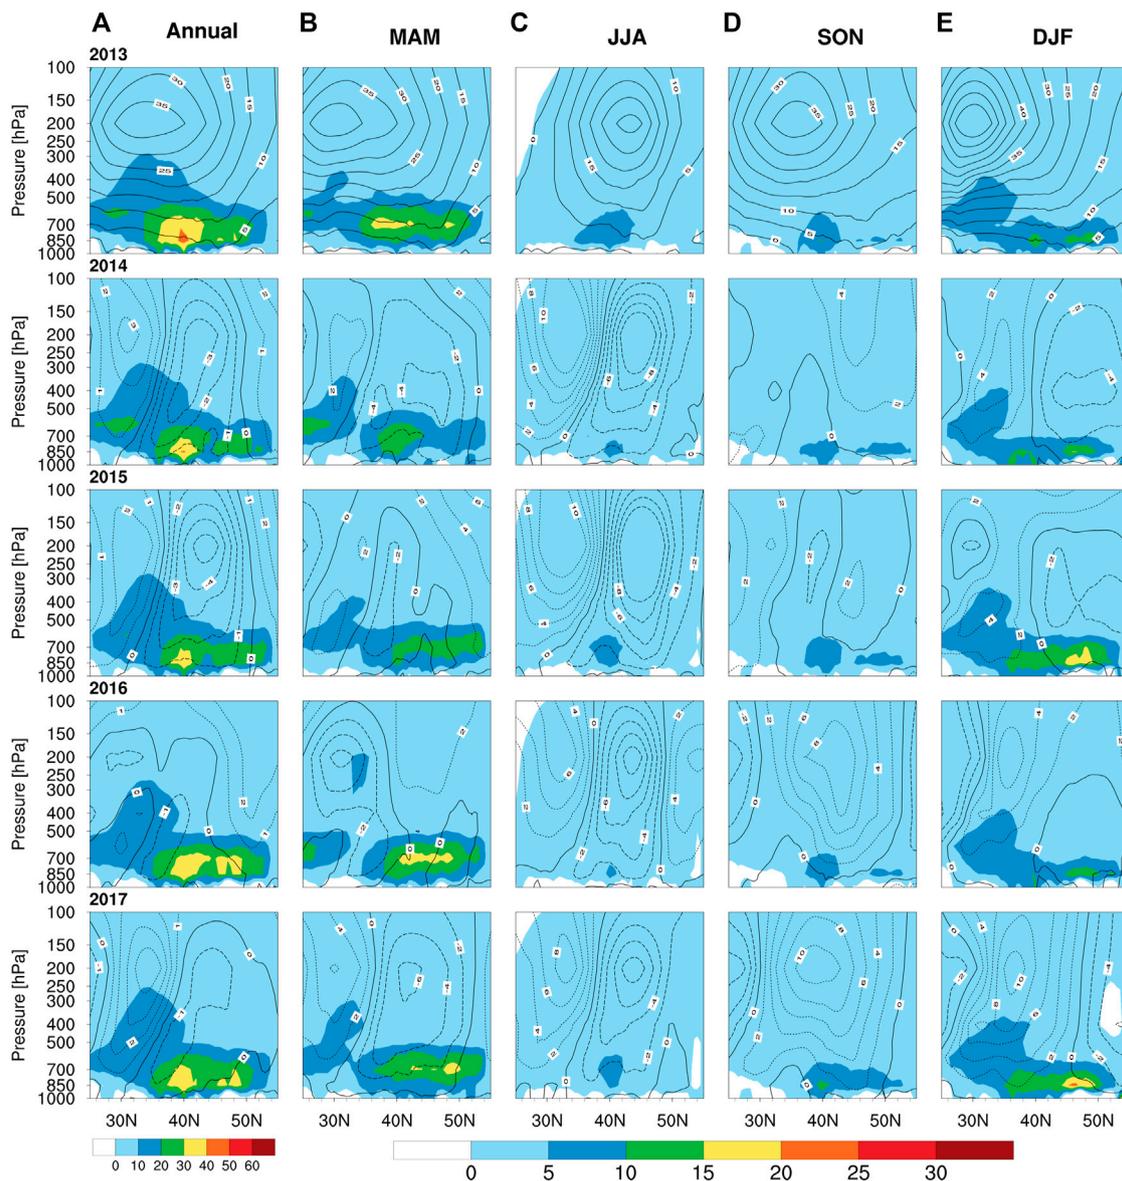

FIGURE 8 | Simulated (A) annual and (B–E) seasonal mass fluxes of PM_{2.5} as well as zonal winds from 2013 to 2017 from the BASE simulation. The mass fluxes of PM_{2.5} are shown by shades (units: 10^6 kg), and winds are represented by contours (units: $m s^{-1}$). The winds in 2013 are represented by solid line (top row). In each of 2014–2017, the differences in zonal winds between this year and 2013 are shown (this year minus 2013) (long dashed lines indicate negative values, short dashed lines indicate positive values, and solid lines indicate no changes in wind speed). Both mass fluxes and winds are those through the meridional plane from the surface to 100 hPa altitude and from 25°N to 55°N along 120°E.

system, creating free NH₃ that reacted with HNO₃ to form NH₄NO₃ (Bae et al., 2021; Uno et al., 2020).

4 DISCUSSION

4.1 The Changes in Mass Outflow From Eastern China During 2013–2017

In order to have a clearer understanding of the impacts of reductions in anthropogenic emissions in China as well as the changes in meteorological conditions on PM_{2.5} in South Korea

and Japan, we analyzed the changes in mass outflow from eastern China during 2013–2017. **Figure 8** shows the simulated annual and seasonal mass fluxes of PM_{2.5} and zonal winds across the selected plane from the surface to 100 hPa altitude and from 25°N to 55°N along 120°E in the BASE simulation. The maximum mass fluxes of PM_{2.5} were located at 700–1,000 hPa. On an annual mean basis, a maximum flux was located over 40°N throughout 2013–2017, and another maximum flux occurred over 46°N in 2016 and 2017 due to the strengthening of the westerlies in this location in MAM and DJF of 2016 and in SON and DJF of 2017.

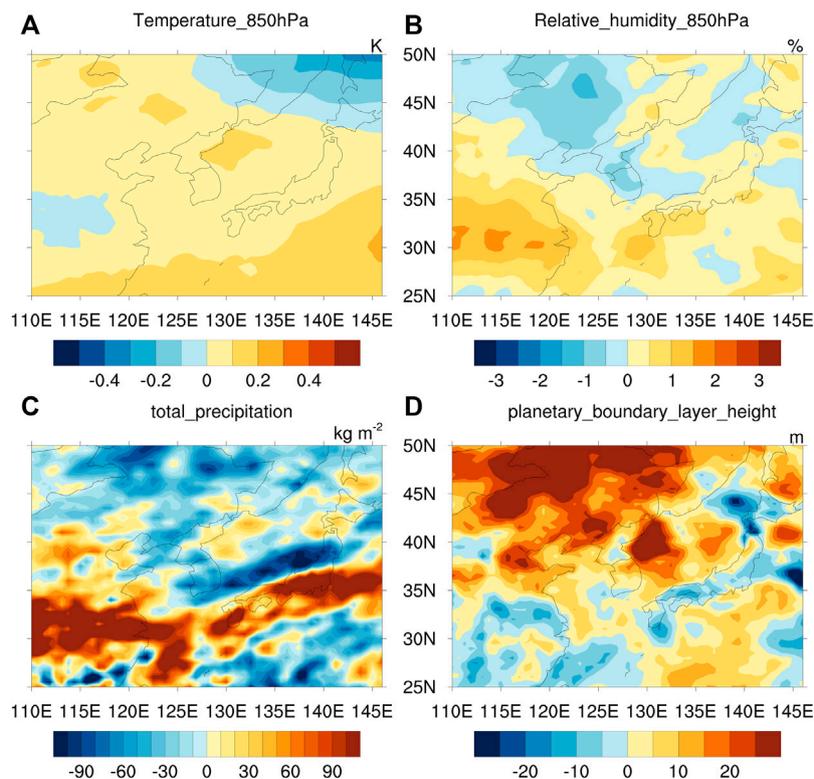

FIGURE 9 | Linear regression trends of annual mean (A) temperature (B) relative humidity, and (D) planetary boundary layer height from 2013 to 2017 (C) Linear regression trends of annual total precipitation from 2013–2017. Temperature, RH, PBLH and precipitation are from the MERRA-2 reanalysis data from the NASA Goddard Earth Sciences (GES) Data and Information Services Center.

TABLE 3 | Simulated outflow of PM_{2.5} from eastern China through the meridional plane from the surface to 100 hPa altitude and from 25°N to 55°N along 120°E. The units are 10⁶ kg season⁻¹ for seasonal fluxes and 10⁶ kg yr⁻¹ for annual fluxes of PM_{2.5}.

year	Annual	MAM	JJA	SON	DJF
2013	4918.5	2162.2	490.0	738.7	1363.2
2014	4414.1	1862.2	449.1	649.9	1358.5
2015	4278.0	1836.8	466.2	688.8	1744.7
2016	4783.5	2116.9	400.2	642.1	1249.2
2017	4799.1	2141.2	475.6	797.0	1597.4

As summarized in **Table 3**, the seasonal outflow flux of PM_{2.5} peaked in MAM of every year as a result of the strong westerlies, although PM_{2.5} levels in MAM in China were not the highest (**Figure 2**). The mass outflow of PM_{2.5} was the lowest in JJA, which was caused by the lowest concentrations of PM_{2.5} in China as well as the weakest westerlies in this season (**Figure 8**). From 2013 to 2017, the annual flux of PM_{2.5} was the highest in 2013 and the lowest in 2015 (**Table 3**). The annual mean westerlies were the weakest over 25°–55°N in 2015 (**Figure 8**). Compared to 2013, the flux of PM_{2.5} decreased by 15.1% in MAM of 2015, but increased by 28.0% in DJF of 2015. These yearly changes in simulated mass fluxes of PM_{2.5} led to corresponding changes in simulated PM_{2.5}

concentrations in South Korea and Japan (Relative to 2013, the PM_{2.5} concentrations in South Korea and Japan from the BASE simulation decreased significantly in MAM of 2015 and increased largely in DJF of 2015, **Figure 5**). The interannual and seasonal variations in mass flux are mainly driven by the changes in meteorological parameters (Holzer et al., 2005; Yang et al., 2015). With the changes in both emissions and meteorology, from 2013 to 2017, the annual mass fluxes of PM_{2.5} from eastern China had a linear increasing trend of 13.1×10^6 kg yr⁻¹ in the BASE simulation. However, the trend of flux was -99.4×10^6 kg yr⁻¹ over 2013–2017 with changes in anthropogenic emissions in China alone (FIXEM_KJ minus FIXEM_CKJ).

4.2 The Impact of Meteorological Conditions on PM_{2.5} Concentration in South Korea and Japan From 2013 to 2017

Over 2013–2017, the changes in meteorological conditions have different effects on PM_{2.5} concentrations in South Korea and Japan. The changes in meteorological conditions led to a decreasing trend of $0.30 \mu\text{g m}^{-3} \text{ year}^{-1}$ in PM_{2.5} concentration in South Korea, whereas an increasing trend of $0.08 \mu\text{g m}^{-3} \text{ year}^{-1}$ in Japan (**Figure 5B**). Therefore, to further understand the impacts of meteorological fields on PM_{2.5} in South Korea and

Japan, we calculated the trends of annual mean temperature, relative humidity (RH) and planetary boundary layer height (PBLH) as well as the trend of annual total precipitation over 2013–2017 (Figure 9).

Temperature and RH can affect the thermodynamics of ammonium nitrate formation. In South Korea, the combined effect of increases in temperature and decreases in RH had an effect of reducing nitrate concentrations from 2013 to 2017 (Zhai et al., 2021) (Figure 7B). In South Korea, from 2013 to 2017, PBLH had an increasing trend, which increased the diffusion of pollutants and also reduced PM_{2.5} concentrations. Although precipitation decreased in South Korea, the overall impact of meteorological conditions in South Korea was to reduce PM_{2.5} over 2013–2017. In Japan, temperature and RH increased whereas PBLH decreased over 2013–2017. The increases in temperature could increase sulfate but reduce nitrate (Aw and Kleeman 2003). Higher RH was reported to increase the formation of secondary aerosols through enhanced chemical reactions (Yin et al., 2016). The decreases in PBLH in Japan restrained vertical mixing and lead to the accumulation of particles (Gao et al., 2015). The spatial distributions of changes in precipitation in Japan were uneven. As a result, the meteorological conditions in Japan led to increases of PM_{2.5}.

5 CONCLUSION

We examined the impacts of reductions in anthropogenic emissions over China and/or changes in meteorological conditions over 2013–2017 on PM_{2.5} and its components in South Korea and Japan. The seasonal variation, interannual variation, and trend of PM_{2.5} and its components in China, South Korea and Japan were simulated using the GEOS-Chem model driven by the MERRA-2 meteorological fields. The impacts of variations in anthropogenic emissions and in meteorological parameters were imposed separately and together by sensitivity studies.

From 2013–2017, with the changes in both anthropogenic emissions and meteorology (BASE simulation), the trends of simulated annual mean PM_{2.5} concentration in eastern China, South Korea, and Japan were -3.33 , -0.66 , and -0.09 $\mu\text{g m}^{-3}$ year⁻¹, respectively, in which the reductions in anthropogenic emissions in China played a dominant role compared to that of meteorology. From 2013 to 2017, the annual mean PM_{2.5} concentrations in eastern China, South Korea, and Japan were reduced by 12.8 (18.5%), 3.0 (8.3%), and 0.36 (2.7%) $\mu\text{g m}^{-3}$, respectively. The reductions in anthropogenic emissions in China (FIXEM_KJ minus FIXEM_CKJ) over 2013–2017 alone led to reductions in annual mean PM_{2.5} concentrations by 13.7 (19.7%), 2.7 (7.7%), and 1.0 (7.9%) $\mu\text{g m}^{-3}$ in eastern China, South Korea, and Japan, respectively. The changes in meteorological fields (FIXEM_CKJ simulation) were also important for PM_{2.5} concentrations in South Korea and Japan. From 2013 to 2017, the changes in meteorological conditions led to reductions in PM_{2.5} concentration in South Korea by 4.7% and increases in PM_{2.5} concentration in Japan by 2.5%.

From 2013 to 2017, the reductions in anthropogenic emissions in China (FIXEM_KJ minus FIXEM_CKJ) also changed the components of PM_{2.5} in South Korea and Japan. The changes

in anthropogenic emissions in China led to reductions in sulfate, ammonium, BC and OC concentrations whereas increases of nitrate in both South Korea and Japan. The reductions in SO₂ emissions in China changed the balance of the ammonia–nitric acid–sulfuric acid–water system, creating free NH₃ that reacted with HNO₃ to form NH₄NO₃. In South Korea, the proportions of sulfate, nitrate, and OC in PM_{2.5} were, respectively, 17.1, 44.4, and 15.8% in 2013, and 14.3, 46.0, and 17.8% in 2017. In Japan, the fractions of sulfate, nitrate, and OC in PM_{2.5} were 27.2, 30.5, and 20.0% in 2013 while 23.7, 33.2, and 21.6% in 2017, respectively. The changes in anthropogenic emissions in China instead of the changes in meteorology dominated this compositional shift.

Model results shown here are helpful for understanding the temporal evolution in the PM_{2.5} on different timescales in the downwind regions of China. Conclusions from this work also have important implications for air quality planning, which needs to account for changes in emissions in the upwind countries. It should be noted that our model results may have uncertainties, especially from the uncertainties in emissions inventories. First, the anthropogenic emissions in other regions except Asia were fixed at the 2013 levels in the BASE simulation, which could not account for the effects of changes in emissions outside Asia. Second, the REAS emission inventory is available only up to 2015, so anthropogenic emissions from REAS in 2016 and 2017 were obtained by linear extrapolation of the values over 2012–2015 for each grid. Third, since we were focused on the impact of the Chinese Governmental “Action Plan on the Prevention and Control of Air Pollution,” we did not account for the role of natural aerosols such as mineral dust and sea salt in this work. All these aspects can be improved in future studies.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

AUTHOR CONTRIBUTIONS

HL designed the study and PX wrote the first version of paper. PX performed model simulations and analyzed the data. HL and PX wrote the final versions of manuscript together.
